Balance a square matrix via LAPACK’s DGEBAL

Description

Balance a square matrix via LAPACK’s DGEBAL. This is an R interface, mainly used for experimentation.

This LAPACK routine is used internally for Eigenvalue decompositions, but also, in Ward(1977)’s algorithm for the matrix exponential.

The name balance() is preferred nowadays, where “dgebal” will probably become deprecated.

Usage

balance(A, job = c("B", "N", "P", "S"))
dgebal(A, job = c("B", "N", "P", "S"))

Arguments

A: a square \((n \times n)\) numeric matrix.

job: a one-letter string specifying the ‘job’ for DGEBAL.

P  Permutation
S  Scaling
B  Both permutation and scaling
N  None

Details

An excerpt of the LAPACK documentation about DGEBAL(), describing the result

\textbf{i1} ("IL0") (output) integer

\textbf{i2} ("IHI") (output) integer

i1 and i2 are set to integers such that on exit \(z[i, j] = 0\) if \(i > j\) and \(j = 1, \ldots, i1 - 1\) or \(i = i2 + 1, \ldots, n\).

If \(\text{job} = 'N'\) or 'S', \(i1 = 1\) and \(i2 = n\).

scale (output) numeric vector of length \(n\). Details of the permutations and scaling factors applied to A. If \(P[j]\) is the index of the row and column interchanged with row and column \(j\) and \(D[j]\) is the scaling factor applied to row and column \(j\), then \(scale[j] = p[j]\) for \(j = 1, \ldots, i1 - 1\) = \(D[j]\) for \(j = i1, \ldots, i2\), = \(p[j]\) for \(j = i2 + 1, \ldots, n\).

The order in which the interchanges are made is \(n\) to \(i2+1\), then \(1\) to \(i1-1\).

Look at the LAPACK documentation for more details.
expAtv

Value

A list with components

- \( z \)  
  the transformation of matrix \( A \), after permutation and or scaling.

- \( \text{scale} \)  
  numeric vector of length \( n \), containing the permutation and/or scale vectors applied.

- \( i1, i2 \)  
  integers (length 1) in \( \{1, 2, \ldots, n\} \), denoted by \( \text{ilo} \) and \( \text{ihi} \) respectively in the LAPACK documentation. Only relevant for "P" or "B", they describe where permutations and where scaling took place; see the Details section.

Examples

```r
m4 <- rbind(c(-1,-1, 0, 0),
           c( 0, 0,10,10),
           c( 0, 0,10, 0),
           c( 0,10, 0, 0))
(b4 <- balance(m4))

#-- for testing and didactical reasons : ----

demo(balanceTst) # also defines the balanceTst() function
# which in its tests ```defines'' what
# the return value means, notably \( (i1,i2,\text{scale}) \)
```

expAtv

\textbf{Compute Matrix Exponential} \( \exp(A t) * v \) \textbf{directly}

Description

Compute \( \exp(A t) * v \) directly, without evaluating \( \exp(A) \).

Usage

```r
expAtv(A, v, t = 1,
       method = "Sidje98",
       rescaleBelow = 1e-6,
       tol = 1e-07, btol = 1e-07, m.max = 30, mxrej = 10,
       verbose = getOption("verbose"))
```
Arguments

- **A**: n x n matrix
- **v**: n - vector
- **t**: number (scalar);
- **method**: a string indicating the method to be used; there's only one currently; we would like to add newer ones.
- **rescaleBelow**: if \( \|A\|_1 \) is smaller than \( \text{rescaleBelow} \), rescale A to norm 1 and t such that \( A^t \) remains unchanged. This step is in addition to Sidje's original algorithm and easily seen to be necessary even in simple cases (e.g., \( n = 3 \)).
- **tol, btol**: tolerances; these are tuning constants of the "Sidje1998" method which the user should typically not change.
- **m.max, mxrej**: integer constants you should only change if you know what you're doing.
- **verbose**: flag indicating if the algorithm should be verbose.

Value

A list with components

- **eAtv**: .....fixme...

Author(s)

Ravi Varadhan, Johns Hopkins University; Martin Maechler (cosmetic, generalization to sparse matrices; rescaling (see \( \text{rescaleBelow} \)).

(s5 <- Matrix(m5 <- rnilMat(5))); v <- c(1,6:9)
(em5 <- expm(m5))
r5 <- expAtv(m5, v)
r5. <- expAtv(s5, v)
stopifnot(all.equal(r5, r5., tolerance = 1e-14),
```
expm

all.equal(c(em5 %*% v), r5$eAtv))

v <- 10:1
with(xct10, all.equal(expm(m), expm))
all.equal(c(xct10$expm %*% v),
          expAtv(xct10$m, v)$eAtv)

expm                  Matrix Exponential

Description
This function computes the exponential of a square matrix \( A \), defined as the sum from \( r = 0 \) to infinity of \( A^r/r! \). Several methods are provided. The Taylor series and Padé approximation are very importantly combined with scaling and squaring.

Usage
expm(x, method = c("Higham08.b", "Higham08",
    "AlMohy-Hi09",
    "R_Eigen", "R_Pade", "R_Ward77", "hybrid_Eigen_Ward"),
    order = 6, trySym = TRUE, tol = .Machine$double.eps, do.sparseMsg = TRUE,
    preconditioning = c("2bal", "1bal", "buggy"))

Arguments

x          a square matrix.
method     "Higham08.b", "Ward77", "Pade" or "Taylor", etc; The default is now "Higham08.b" which uses Higham’s 2008 algorithm with additional balancing preconditioning, see expm.Higham08.
            The versions with "*O" call the original Fortran code, whereas the first ones call the BLAS-using and partly simplified newer code.
            "R_Pade" uses an R-code version of "Pade" for didactical reasons, and "R_Ward77" uses an R version of "Ward77", still based on LAPACK’s dgebal, see R interface dgebal. This has enabled us to diagnose and fix the bug in the original octave implementation of "Ward77". "R_Eigen" tries to diagonalise the matrix x, if not possible, "R_Eigen" raises an error. "hybrid_Eigen_Ward" method also tries to diagonalise the matrix x, if not possible, it uses "Ward77" algorithm.
order      an integer, the order of approximation to be used, for the "Pade" and "Taylor" methods. The best value for this depends on machine precision (and slightly on x) but for the current double precision arithmetic, one recommendation (and the Matlab implementations) uses order = 6 unconditionally; our default, 8, is from Ward(1977, p.606)'s recommendation, but also used for "AlMohy-Hi09" where a high order order=12 may be more appropriate (and slightly more expensive).
trySym logical indicating if method = "R_Eigen" should use \texttt{isSymmetric}(x) and take advantage for (almost) symmetric matrices.

tol a given tolerance used to check if x is computationally singular when method = "hybrid_Eigen_Ward".

do.sparseMsg logical allowing a message about sparse to dense coercion; setting it FALSE suppresses that message.

preconditioning a string specifying which implementation of Ward(1977) should be used when method = "Ward77".

Details

The exponential of a matrix is defined as the infinite Taylor series

\[ e^M = \sum_{k=1}^{\infty} \frac{M^k}{k!}. \]

For the "Pade" and "Taylor" methods, there is an "accuracy" attribute of the result. It is an upper bound for the L2 norm of the Cauchy error expm(x, *, order + 10) - expm(x, *, order).

Currently, only algorithms which are "R-code only" accept sparse matrices (see the \texttt{sparseMatrix} class in package \texttt{Matrix}), i.e., currently only "R_Eigen" and "Higham08".

Value

The matrix exponential of \( x \).

Note

For a good general discussion of the matrix exponential problem, see Moler and van Loan (2003).

Author(s)

The "Ward77" method:
Vincent Goulet <vincent.goulet@act.ulaval.ca>, and Christophe Dutang, based on code translated by Doug Bates and Martin Maechler from the implementation of the corresponding Octave function contributed by A. Scottedward Hodel <A.S.Hodel@eng.auburn.edu>.

The "PadeRB5" method:
Roger B. Sidje, see the EXPOKIT reference.

The "Pade0" and "Taylor0" methods:
Marina Shapira (U Oxford, UK) and David Firth (U Warwick, UK);

The "Pade" and "Taylor" methods are slight modifications of the "O" (O)riginal versions) methods, by Martin Maechler, using BLAS and LINPACK where possible.

The "hybrid_Eigen_Ward" method by Christophe Dutang is a C translation of "R_Eigen" method by Martin Maechler.

The "Higham08" and "Higham08.b" (current default) were written by Michael Stadelmann, see \texttt{expm.Higham08}.

The "AlMohy+Hi09" implementation (\texttt{R} code interfacing to stand-alone C) was provided and donated by Drew Schmidt, U. Tennesses.

expm(test2, method="R_Eigen")

expm(test3, method="R_Eigen")

expm(test4, method="R_Eigen")

**Description**

Calculation of matrix exponential $e^A$ with the 'Scaling & Squaring' method with balancing.

Implementation of Higham’s Algorithm from his book (see references), Chapter 10, Algorithm 10.20.

The balancing option is an extra from Michael Stadelmann’s Masters thesis.

**Usage**

```r
expm.Higham08(A, balancing = TRUE)
```

**Arguments**

- **A**
  - square matrix, may be a "sparseMatrix", currently only if balancing is false.

- **balancing**
  - logical indicating if balancing should happen (before and after scaling and squaring).
Details

The algorithm comprises the following steps

1. Balancing
2. Scaling
3. Padé-Approximation
4. Squaring
5. Reverse Balancing

Value

A matrix of the same dimension as \( A \), the matrix exponential of \( A \).

Author(s)

Michael Stadelmann (final polish by Martin Maechler).

expmCond

**Exponential Condition Number of a Matrix**

**Description**

Compute the exponential condition number of a matrix, either with approximation methods, or exactly and very slowly.

**Usage**

```r
expmCond(A, method = c("1.est", "F.est", "exact"),
        expm = TRUE, abstol = 0.1, reltol = 1e-6,
        give.exact = c("both", "1.norm", "F.norm"))
```

**Arguments**

- `A`: a square matrix
- `method`: a string; either compute 1-norm or F-norm approximations, or compute these exactly.
- `expm`: logical indicating if the matrix exponential itself, which is computed anyway, should be returned as well.
- `abstol`, `reltol`: for `method = "F.est"`, numerical ≥ 0, as absolute and relative error tolerance.
- `give.exact`: for `method = "exact"`, specify if only the 1-norm, the Frobenius norm, or both are to be computed.

**Details**

- `method = "exact"`, aka Kronecker-Sylvester algorithm, computes a Kronecker matrix of dimension $n^2 \times n^2$ and hence, with $O(n^5)$ complexity, is prohibitely slow for non-small $n$. It computes the exact exponential-condition numbers for both the Frobenius and/or the 1-norm, depending on `give.exact`.

  The two other methods compute approximations, to these norms, i.e., estimate them, using algorithms from Higham, chapt.-3.4, both with complexity $O(n^3)$. 

---
Value

when expm = TRUE, for method = "exact", a list with components

expm containing the matrix exponential, expm.Higham08(A).

expmCond(F|1) numeric scalar, (an approximation to) the (matrix exponential) condition number, for either the 1-norm (expmCond1) or the Frobenius-norm (expmCondF).

When expm is false and method one of the approximations ("*.est"), the condition number is returned directly (i.e., numeric of length one).

Author(s)

Michael Stadelmann (final polish by Martin Maechler).

expmFrechet

Frechet Derivative of the Matrix Exponential

Description

Compute the Frechet (actually ‘Fréchet’) derivative of the matrix exponential operator.

Usage

expmFrechet(A, E, method = c("SPS", "blockEnlarge"), expm = TRUE)

Arguments

- **A**: square matrix \((n \times n)\).
- **E**: the “small Error” matrix, used in \(L(A, E) = f(A + E, A)\)
- **method**: string specifying the method / algorithm; the default "SPS" is “Scaling + Padé + Squaring” as in the algorithm 6.4 below; otherwise see the ‘Details’ section.
- **expm**: logical indicating if the matrix exponential itself, which is computed anyway, should be returned as well.

Details

Calculation of \(e^A\) and the Exponential Frechet-Derivative \(L(A, E)\).

When `method` = "SPS" (by default), the with the Scaling - Padé - Squaring Method is used, in an R-Implementation of Al-Mohy and Higham (2009)'s Algorithm 6.4.

- **Step 1**: Scaling (of A and E)
- **Step 2**: Padé-Approximation of \(e^A\) and \(L(A, E)\)
- **Step 3**: Squaring (reversing step 1)

`method = "blockEnlarge"` uses the matrix identity of

\[
f([AE; 0A]) = [f(A)Df(A); 0f(A)]
\]

for the \(2n \times 2n\) block matrices where \(f(A) := \expm(A)\) and \(Df(A) := L(A, E)\). Note that "blockEnlarge" is much simpler to implement but slower (CPU time is doubled for \(n = 100\)).

Value

a list with components

- **expm**: if `expm` is true, the matrix exponential \((n \times n)\) matrix).
- **Lexpm**: the Exponential-Frechet-Derivative \(L(A, E)\), a matrix of the same dimension.

Author(s)

Michael Stadelmann (final polish by Martin Maechler).
logm

Matrix Logarithm

Description
This function computes the (principal) matrix logarithm of a square matrix. A logarithm of a matrix \( A \) is \( L \) such that \( A = e^L \) (meaning \( A = \expm(L) \)), see the documentation for the matrix exponential, \( \expm \), which can be defined as

\[
e^L := \sum_{r=0}^{\infty} \frac{L^r}{r!}.
\]

Usage
logm(x, method = c("Higham08", "Eigen"),

tol = .Machine$double.eps)

Arguments
\( x \) a square matrix.

method a string specifying the algorithmic method to be used. The default uses the algorithm by Higham(2008).

The simple "Eigen" method tries to diagonalise the matrix \( x \); if that is not possible, it raises an error.

tol a given tolerance used to check if \( x \) is computationally singular when method = "Eigen".
Details

The exponential of a matrix is defined as the infinite Taylor series

\[ e^M = \sum_{k=1}^{\infty} \frac{M^k}{k!}. \]

The matrix logarithm of \( A \) is a matrix \( M \) such that \( \exp(M) = A \). Note that there typically are an infinite number of such matrices, and we compute the principal matrix logarithm, see the references.

Method "Higham08" works via "inverse scaling and squaring", and from the Schur decomposition, applying a matrix square root root computation. It is somewhat slow but also works for non-diagonalizable matrices.

Value

A matrix ‘as x’ with the matrix logarithm of \( x \), i.e., `all.equal( expm(logm(x)), x, tol) is typically true for quite small tolerance tol`.

Author(s)

Method "Higham08" was implemented by Michael Stadelmann as part of his master thesis in mathematics, at ETH Zurich; the "Eigen" method by Christophe Dutang.

`expm`

Examples

```r
m <- diag(2)
logm(m)
expm(logm(m))

## Here, logm() is barely defined, and Higham08 has needed an amendment
## in order for not to loop forever:
D0 <- diag(x=c(1, 0.))
(L. <- logm(D0))
stopifnot(all.equal(D0, expm(L.)) )

## A matrix for which clearly no logm(.) exists:
(m <- cbind(1:2, 1))
(1.m <- logm(m)) ## all NA
stopifnot(is.na(1.m))
```
## Description

Compute the $k$-th power of a matrix. Whereas $x^k$ computes element wise powers, $x \%\% k$ corresponds to $k - 1$ matrix multiplications, $x \%\% x \%\% \ldots \%\% x$.

### Usage

$x \%\% k$

### Arguments

- **x** a square matrix.
- **k** an integer, $k \geq 0$.

### Details

Argument $k$ is coerced to integer using `as.integer`. The algorithm uses $O(\log_2(k))$ matrix multiplications.

### Value

A matrix of the same dimension as $x$.

### Note

If you think you need $x^k$ for $k < 0$, then consider instead `solve(x \%\% (-k))`.

### Author(s)

Based on an R-help posting of Vicente Canto Casasola, and Vincent Goulet’s C implementation in `actuar`.

### See Also

`%*%` for matrix multiplication.

### Examples

```r
A <- cbind(1, 2 * diag(3)[,-1])
A
A \%\% 2
stopifnot(identical(A, A \%\% 1),
          A \%\% 2 == A \%\% 2)
```
**Description**

Stig Mortensen wrote on Oct 22, 2007 to the authors of the **Matrix** package with subject “Strange result from expm”. There, he presented the following $8 \times 8$ matrix for which the Matrix `expm()` gave a “strange” result. As we later researched, the result indeed was wrong: the correct entries were wrongly permuted. The reason has been in the underlying source code in Octave from which it had been ported to **Matrix**.

**Usage**

data(matStig)

**Author(s)**

Martin Maechler

**Examples**

data(matStig)

as(matStig, "sparseMatrix") # since that prints more nicely.

## For more compact printing:

op <- options(digits = 4)

E1 <- expm(matStig, "Ward77", preconditioning="buggy") # the wrong result
as(E1, "sparseMatrix")
str(E2 <- expm(matStig, "Pade")) # the correct one (has "accuracy" attribute)
as(E2, "sparseMatrix")
attr(E2,"accuracy") <- NULL # don't want it below
E3 <- expm(matStig, "R_Eigen") # even that is fine here
all.equal(E1,E2) # not at all equal (rel.difference >= 1.)
stopifnot(all.equal(E3,E2)) # ==

##________ The "proof" that "Ward77" is wrong _________

M <- matStig
E1 <- expm(t(M), "Ward77", precondition = "buggy")
E2 <- expm(t(M), "Pade"); attr(E2,"accuracy") <- NULL
all.equal(E1, t(E1)) # completely different (rel.diff ~ 1.7 (platform dep.))
stopifnot(all.equal(Et2, t(E2))) # the same (up to tolerance)

options(op)
Description

This function computes the matrix square root of a square matrix. The sqrt of a matrix \( A \) is \( S \) such that \( A = SS \).

Usage

\[
sqrtm(x)
\]

Arguments

\( x \)  a square matrix.

Details

The matrix square root \( S \) of \( M \), \( S = sqrtm(M) \) is defined as one (the “principal”) \( S \) such that \( SS = S^2 = M \), (in \( \mathbb{R} \), \( \text{all.equal} ( S \ %%\% \ S , M ) \)).

The method works from the Schur decomposition.

Value

A matrix ‘as \( x \)’ with the matrix sqrt of \( x \).

Author(s)

Michael Stadelmann wrote the first version.
