Package ‘magic’

September 17, 2018

Version 1.5-9
Date 2018-09-14
Title Create and Investigate Magic Squares
Author Robin K. S. Hankin
Depends R (>= 2.10), abind
Description A collection of efficient, vectorized algorithms for the creation and investigation of magic squares and hypercubes, including a variety of functions for the manipulation and analysis of arbitrarily dimensioned arrays. The package includes methods for creating normal magic squares of any order greater than 2. The ultimate intention is for the package to be a computerized embodiment of all magic square knowledge, including direct numerical verification of properties of magic squares (such as recent results on the determinant of odd-ordered semimagic squares). Some antimagic functionality is included. The package also serves as a rebuttal to the often-heard comment “I thought R was just for statistics”.

arot(a)
arow(a,1)
```

```r
adiag
```

* Binds arrays corner-to-corner

Description

Array generalization of `blockdiag()`

Usage

```r
adiag(..., pad=as.integer(0), do.dimnames=TRUE)
```
Arguments

... Arrays to be binded together
pad Value to pad array with; note default keeps integer status of arrays
do.dimnames Boolean, with default TRUE meaning to return dimnames if possible. Set to FALSE if performance is an issue

Details

Binds any number of arrays together, corner-to-corner. Because the function is associative provided pad is of length 1, this page discusses the two array case.

Suppose $x \leftarrow \text{adiag}(a, b)$ and $\text{dim}(a) = c(a_1, \ldots, a_d)$, $\text{dim}(b) = c(b_1, \ldots, b_d)$. Then we have all($\text{dim}(x) = \text{dim}(a) + \text{dim}(b)$) and $x[1:a_1, \ldots, 1:a_d] = a$ and $x[(a_1+1):(a_1+b_1), \ldots, (a_d+1):(a_d+b_d)] = b$.

Dimnames are preserved, if both arrays have non-null dimnames, and do.dimnames is TRUE.

Argument pad is usually a length-one vector, but any vector is acceptable; standard recycling is used. Be aware that the output array (of dimension $\text{dim}(a) + \text{dim}(b)$) is filled with (copies of) pad before $a$ and $b$ are copied. This can be confusing.

Value

Returns an array of dimensions $\text{dim}(a) + \text{dim}(b)$ as described above.

Note

In \text{adiag}(a, b), if $a$ is a length-one vector, it is coerced to an array of dimensions $\text{rep}(1, \text{length}(\text{dim}(b)))$; likewise $b$. If both $a$ and $b$ are length-one vectors, return $\text{diag}(c(a, b))$.

If $a$ and $b$ are arrays, function \text{adiag()} requires $\text{length}(\text{dim}(a)) = \text{length}(\text{dim}(b))$ (the function does not guess which dimensions have been dropped; see examples section). In particular, note that vectors are not coerced except if of length one.

\text{adiag()} is used when padding magic hypercubes in the context of evaluating subarray sums.

Author(s)

Peter Wolf with some additions by Robin Hankin

See Also

\text{subsums}, \text{apad}

Examples

```r
a <- array(1,c(2,2))
b <- array(-1,c(2,2))
adiag(a, b)

# dropped dimensions can count:

b2 <- b1 <- b
dim(a) <- c(2,1,2)
```
allsubhypercubes

Description

Extracts all subhypercubes from an n-dimensional hypercube.

Usage

allsubhypercubes(a)

Arguments

a

The magic hypercube whose subhypercubes are computed
Value

Returns a list, each element of which is a subhypercube of a. Note that major diagonals are also returned (as n-by-1 arrays).

The names of the list are the extracted subhypercubes. Consider a <- magichypercube.4n(1, d=4) (so n=4) and if jj <- allsubhypercubes(a), consider jj[9]. The name of jj[9] is "n-i+1, i, i,"; its value is a square matrix. The columns of jj[9] may be recovered by a[n-i+1, i, i,] with i = 1...n (NB: that is, jj[9] == cbind(a[n-1+1,1,1,], a[n-2+1,2,2,], a[n-3+1,3,3,], a[n-4+1,4,4,]) where n=4).

The list does not include the whole array.

Note

This function is a dog’s dinner. It’s complicated, convoluted, and needs an absurd use of the eval(parse(text=...)) construction. Basically it sucks big time.

BUT...I cannot for the life of me see a better way that gives the same results, without loops, on hypercubes of arbitrary dimension.

On my 256MB Linuxbox, allsubhypercubes() cannot cope with d as high as 5, for n=4. Heigh ho.

The term “subhypercube” does not include diagonally oriented entities at is.magichypercube. But it does here.

is.perfect

Examples

a <- magichypercube.4n(1, d=4)
allsubhypercubes(a)

allsums

Row, column, and two diagonal sums of arrays

Description

Returns all rowsums, all columnsums, and all (broken) diagonal sums of a putative magic square.

Usage

allsums(m, func=NULL, ...)

6

allsums
Arguments

m  The square to be tested
func  Function, with default NULL interpreted as `sum()`, to be applied to the square rowwise, columnwise, and diagonalwise
...
Further arguments passed to `func()`

Value

Returns a list of four elements. In the following, “sums” means “the result of applying `func()`”.

rowsums  All n row sums
colsums  All n column sums
majors  All n broken major diagonals (northwest-southeast). First element is the long (unbroken) major diagonal, tested by `is.magic()`
minors  All n broken minor diagonals (northeast-southwest). First element is the long (unbroken) minor diagonal.

Note

If `func()` returns a vector, then the `allsums()` returns a list whose columns are the result of applying `func()`. See third and fourth examples below.

Used by `is.magic()` et seq.
The major and minor diagonals would benefit from being recoded in C.

allsums(magic(7), sort)
  # beware! compare apply(magic(7), 1, sort) and apply(magic(7), 2, sort)
```
Description

Generalized padding for arrays of arbitrary dimension

Usage

apad(a, 1, e = NULL, method = "ext", post = TRUE)

Arguments

- **a**: Array to be padded
- **1**: Amount of padding to add. If a vector of length greater than one, it is interpreted as the extra extent of a along each of its dimensions (standard recycling is used). If of length one, interpret as the dimension to be padded, in which case the amount is given by argument 1.
- **e**: If 1 is of length one, the amount of padding to add to dimension 1
- **method**: String specifying the values of the padded elements. See details section.
- **post**: Boolean, with default TRUE meaning to append to a and FALSE meaning to prepend.

Details

Argument method specifies the values of the padded elements. It can be either “ext”, “mirror”, or “rep”.

Specifying ext (the default) uses a padding value given by the “nearest” element of a, as measured by the Manhattan metric.

Specifying mirror fills the array with alternate mirror images of a; while rep fills it with unreflected copies of a.

Note

Function apad() does not work with arrays with dimensions of zero extent: what to pad it with? To pad with a particular value, use adiag().

The function works as expected with vectors, which are treated as one-dimensional arrays. See examples section.

Function apad() is distinct from adiag(), which takes two arrays and binds them together. Both functions create an array of the same dimensionality as their array arguments but with possibly larger extents. However, the functions differ in the values of the new array elements. Function adiag() uses a second array; function apad() takes the values from its primary array argument.

Replacements for APL functions take and drop

**Description**

Replacements for APL functions take and drop

**Usage**

```
apldrop(a, b, give.indices=FALSE)
apldrop(a, b) <- value
apltake(a, b, give.indices=FALSE)
apltake(a, b) <- value
```

**Arguments**

- **a**: Array
- **b**: Vector of number of indices to take/drop. Length of b should not exceed `length(dim(a))`; if it does, an error is returned
- **give.indices**: Boolean, with default FALSE meaning to return the appropriate subset of array a, and TRUE meaning to return the list of the selected elements in each of the dimensions. Setting to TRUE is not really intended for the end-user, but is used in the code of `apltake<-()` and `apldrop<-()`
- **value**: elements to replace

---

**Examples**

```
apad(1:10,4,method="mirror")
apad(1:10,4,method="mirror")
apad(a,c(4,4))
apad(a,c(4,4),post=FALSE)
apad(a,1,5)
apad(a,c(5,6),method="mirror")
apad(a,c(5,6),method="mirror",post=FALSE)
```

---
Details

`apltake(a, b)` returns an array of the same dimensionality as `a`. Along dimension `i`, if `b[i]>0`, the first `b[i]` elements are retained; if `b[i]<0`, the last `b[i]` elements are retained.

`apldrop(a, b)` returns an array of the same dimensionality as `a`. Along dimension `i`, if `b[i]>0`, the first `b[i]` elements are dropped if `b[i]<0`, the last `b[i]` elements are dropped.

These functions do not drop singleton dimensions. Use `drop()` if this is desired.

Author(s)

Robin K. S. Hankin

Examples

```r
a <- magichypercube.4n(m=1)
apltake(a, c(2,3,2))
apldrop(a, c(1,1,2))

b <- matrix(1:30,5,6)
apldrop(b, c(1,-2)) <- -1

b <- matrix(1:110,10,11)
apltake(b, 2) <- -1
apldrop(b, c(5,-7)) <- -2
```

---

aplus

**Generalized array addition**

Description

Given two arrays `a` and `b` with `length(dim(a))==length(dim(b))`, return a matrix with dimensions `pmax(dim(a), dim(b))` where “overlap” elements are `a+b`, and the other elements are either 0, `a`, or `b` according to location. See details section.

Usage

`aplus(...)`

Arguments

```r
... numeric or complex arrays
```
Details

The function takes any number of arguments (the binary operation is associative).

The operation of \texttt{aplus()} is understandable by examining the following \texttt{pseudo} code:

\begin{itemize}
  \item \texttt{outa <- array(0,pmax(a,b))}
  \item \texttt{outb <- array(0,pmax(a,b))}
  \item \texttt{outa[1:dim(a)] <- a}
  \item \texttt{outb[1:dim(a)] <- b}
  \item \texttt{return(outa+outb)}
\end{itemize}

See how \texttt{outa} and \texttt{outb} are the correct size and the appropriate elements of each are populated with \texttt{a} and \texttt{b} respectively. Then the sum is returned.

\texttt{aplus(rbind(1:9),cbind(1:9))}
\end{quote}

\begin{quote}
a <- matrix(1:8,2,4)
b <- matrix(1:10,5,2)
aplus(a*100,b,b)
\end{quote}

\texttt{arev} \hspace{1cm} \textit{Reverses some dimensions; a generalization of \texttt{rev}}

Description

A multidimensional generalization of \texttt{rev()} : given an array \texttt{a}, and a Boolean vector \texttt{swap}, return an array of the same shape as \texttt{a} but with dimensions corresponding to \texttt{TRUE} elements of \texttt{swap} reversed. If \texttt{swap} is not Boolean, it is interpreted as the dimensions along which to swap.

Usage

\begin{quote}
\texttt{arev(a, swap = TRUE)}
\end{quote}
Arguments

- `a` Array to be reversed
- `swap` Vector of Boolean variables. If `swap[i]` is TRUE, then dimension `i` of array `a` is reversed. If `swap` is of length one, recycle to `length(dim(a))`

Details

If `swap` is not Boolean, it is equivalent to `1:n %in% swap` (where `n` is the number of dimensions). Thus multiple entries are ignored, as are entries greater than `n`.

If `a` is a vector, `rev(a)` is returned.

Function `arev()` handles zero-extent dimensions as expected.

Function `arev()` does not treat singleton dimensions specially, and is thus different from Octave’s `flipdim()`, which (if supplied with no second argument) flips the first nonsingleton dimension. To reproduce this, use `arev(a, fnsd(a))`.

Author(s)

Robin K. S. Hankin

See Also

`ashift`

Examples

```r
a <- matrix(1:42,6,7)
arev(a) #Note swap defaults to TRUE

b <- magichypercube.4n(1,d=4)
arev(b,c(TRUE,FALSE,TRUE,FALSE))
```

Description

Rotates an array about two specified dimensions by any number of 90 degree turns

Usage

```r
arot(a, rights = 1, pair=1:2)
```

Arguments

- `a` The array to be rotated
- `rights` Integer; number of right angles to turn
- `pair` A two-element vector containing the dimensions to rotate with default meaning to rotate about the first two dimensions
Note
Function arot() is not exactly equivalent to octave's rotdim(); in arot() the order of the elements of pair matters because the rotation is clockwise when viewed in the (pair[1], pair[2]) direction. Compare octave's rotdim() in which pair is replaced with sort(pair).
Note also that the rotation is about the first two dimensions specified by pair but if pair has more than two elements then these dimensions are also permuted.
Also note that function arot() does not treat singleton dimensions specially.

Author(s)
Robin K. S. Hankin

See Also
arev

Examples
a <- array(1:16,rep(2,4))
aro(a)

Description
Given an array, returns an array of the same size whose elements are sequentially numbered along the $i^{th}$ dimension.

Usage
aro(a, i)

Arguments
a array to be converted
i Number of the dimension

Value
An integer matrix with the same dimensions as a, with element $(n_1, n_2, \ldots n_d)$ being $n_i$.

Note
This function is equivalent to, but faster than, function(a,i)(do.index(a, function(x){x[i]})). However, it is much more complicated.
The function is nominally the same as slice.index() but I have not checked all the edge cases.
as.standard

Author(s)
Robin K. S. Hankin

Examples

```r
a <- array(0, c(3,3,2,2))
arow(a,2)
(arrow(a,1)+arrow(a,2)+arrow(a,3)+arrow(a,4))%%2
```

---

**as.standard**

*Standard form for magic squares*

Description

Transforms a magic square or magic hypercube into Frenicle’s standard form.

Usage

```r
as.standard(a, toroidal = FALSE, one_minus=FALSE)
is.standard(a, toroidal = FALSE, one_minus=FALSE)
```

Arguments

- `a`: Magic square or hypercube (array) to be tested or transformed.
- `toroidal`: Boolean, with default FALSE meaning to use Frenicle’s method, and TRUE meaning to use additional transformations appropriate to toroidal connectivity.
- `one_minus`: Boolean, with TRUE meaning to use the transformation \(x \rightarrow n^2 + 1 - x\) if appropriate, and default FALSE meaning not to use this.

Details

For a square, `as.standard()` transforms a magic square into Frenicle’s standard form. The four numbers at each of the four corners are determined. First, the square is rotated so the smallest of the four is at the upper left. Then, element \([1,2]\) is compared with element\([2,1]\) and, if it is larger, the transpose is taken.

Thus all eight rotated and transposed versions of a magic square have the same standard form.

The square returned by `magic()` is in standard form.

For hypercubes, the algorithm is generalized. First, the hypercube is reflected so that \([a,QLQLNNNLQLQ]\) is the smallest of the \(2^d\) corner elements (eg \([a,QLnLQLNNNLQLQ]\)).

Next, `aperm()` is called so that

\[
a[1,1,\ldots,1,1] < a[1,1,\ldots,2,1] < \ldots < a[2,1,\ldots,1,1].
\]

Note that the inequalities are strict as hypercubes are assumed to be normal. As of version 1.3-1, `as.standard()` will accept arrays of any dimension (ie arrays `a` with `minmax(dim(a))==FALSE` will be handled sensibly).
An array with any dimension of extent zero is in standard form by definition; dimensions of length one are dropped.

If argument toroidal is TRUE, then the array a is translated using ashift() so that a[1,1,...,1] == min(a). Such translations preserve the properties of semimagicness and pandiagonalness (but not magicness or associativity).

It is easier (for me at least) to visualise this by considering two-dimensional arrays, tiling the plane with copies of a.

Next, the array is shifted so that a[2,1,...,1] < a[1,dim(a)[1],1,...,1] and a[1,2,...,1] < a[1,dim(a)[2],1,...,1] and so on.

Then aperm() is called as per the non-toroidal case above.

is.standard() returns TRUE if the magic square or hypercube is in standard form. is.standard() and as.standard() check for neither magicness nor normality (use is.magic and is.normal for this).

Note

There does not appear to be a way to make the third letter of “Frenicle” have an acute accent, as it should do.

## but not magicness:
is.magic(as.standard(magic(10),TRUE))
A class of multiplicative magic squares due to Cilleruelo and Luca

Description

Cilleruelo and Luca give a class of multiplicative magic squares whose behaviour is interesting.

Usage

cilleruelo(n, m)

Arguments

n, m

Arguments: usually integers

Details

\[
\begin{pmatrix}
(n + 2)(m + 0) & (n + 3)(m + 3) & (n + 1)(m + 2) & (n + 0)(m + 1) \\
(n + 1)(m + 1) & (n + 0)(m + 2) & (n + 2)(m + 3) & (n + 3)(m + 0) \\
(n + 0)(m + 3) & (n + 1)(m + 0) & (n + 3)(m + 1) & (n + 2)(m + 2) \\
(n + 3)(m + 2) & (n + 2)(m + 1) & (n + 0)(m + 0) & (n + 1)(m + 3)
\end{pmatrix}
\]

Value

Returns a 4 × 4 matrix.

       lty=1:3,col=1:3)
```

circulant

Circulant matrices of any order

Description

Creates and tests for circulant matrices of any order

Usage

```r
circulant(vec,doseq=TRUE)
is.circulant(m,dir=rep(1,length(dim(m))))
```

Arguments

- `vec, doseq`: In `circulant()`, vector of elements of the first row. If `vec` is of length one, and `doseq` is `TRUE`, then interpret `vec` as the order of the matrix and return a circulant with first row `seq_len(vec)`
- `m`: In `is.circulant()`, matrix to be tested for circulantism
- `dir`: In `is.circulant()`, the direction of the diagonal. In a matrix, the default value (`c(1,1)`) traces the major diagonals

Details

A matrix $a$ is circulant if all major diagonals, including broken diagonals, are uniform; ie if $a_{ij} = a_{k,l}$ when $i - j = k - l$ (modulo $n$). The standard values to use give 1:n for the top row.

In function `is.circulant()`, for arbitrary dimensional arrays, the default value for `dir` checks that $a[v]=a[v+rep(1,d)]=...=a[v+rep((n-1),d)]$ for all `v` (that is, following lines parallel to the major diagonal); indices are passed through `process()`.

For general `dir`, function `is.circulant()` checks that $a[v]=a[v+dir]=a[v+2*dir]=...=a[v+(n-1)*d]$ for all `v`.

A Toeplitz matrix is one in which $a[i,j]=a[i',j']$ whenever $|i-j|=|i'-j'|$. See function `toeplitz()` of the stats package for details.

cube2

A pantriagonal magic cube

Description

A pantriagonal magic cube of order 4 originally due to Hendricks

Usage

data(cube2)

Details

Meaning of “pantriagonal” currently unclear

Source

Hendricks

Examples

data(cube2)
is.magichypercube(cube2)
is.perfect(cube2)
Description

Returns broken diagonals of a magic square

Usage

diag.off(a, offset = 0, nw.se = TRUE)

Arguments

a          Square matrix
offset      vertical offset
nw.se       Boolean variable with TRUE meaning trace diagonals along the northwest-southeast
direction (point [1,n] to [n,1]).

Details

Useful when testing for panmagic squares. The first element is always the unbroken one (ie [1,1] to [n,n] if nw.se is TRUE and [1,n] to [n,1] if nw.se is FALSE.

Author(s)

Robin K. S. Hankin

diag.off(magic(10),nw.se=FALSE,offset=1)
Apply a function to array element indices

Description

Given a function \( f() \) that takes a vector of indices, and an array of arbitrary dimensions, apply \( f() \) to the elements of \( a \)

Usage

\[
\text{do.index}(a, f, \ldots)
\]

Arguments

- \( a \) : Array
- \( f \) : Function that takes a vector argument of the same length as \( \text{dim}(a) \)
- \( \ldots \) : Further arguments supplied to \( f() \)

Value

Returns a matrix of the same dimensions as \( a \)

Note

Tamas Papp suggests the one-liner

\[
\text{function}(a, f, \ldots)(\text{array(apply(as.matrix(expand.grid(lapply(dim(a),\text{seq_len})),\text{KEEP.OUT.ATTRS=FAL})))})
\]

which is functionally identical to \( \text{do.index}() \); but it is no faster than the version implemented in the package, and (IMO) is harder to read.

Further note that function \( \text{arow}() \) is much much faster than \( \text{do.index}() \); it is often possible to rephrase a call to \( \text{do.index}() \) as a call to \( \text{arow}() \); do this where possible unless the additional code opacity outweighs the speed savings.

Author(s)

Robin K. S. Hankin, with improvements by Gabor Grothendieck and Martin Maechler, via the R help list

\( \text{arow} \)
Examples

\begin{verbatim}
a <- array(0,c(2,3,4))
b <- array(rpois(60,1),c(3,4,5))
f1 <- function(x)(sum(x))
f2 <- function(x)(sum((x-1)^2))
f3 <- function(x)(b[t(x)])
f4 <- function(x)(sum(x)%%2)
f5 <- function(x,u){x[u]}
do.index(a,f1)  # should match arow(a,1)+arow(a,2)+arow(a,3)
do.index(a,f2)
do.index(a,f3)  # same as apltake(b,dim(a))
do.index(a,f4)  # Male/female toilets at NOC

do.index(a,f5,2)  # same as arow(a,2)
\end{verbatim}

Description

Compares two magic squares according to Frenicle’s method. Mnemonic is the old Fortran “.GT.” (for “Greater Than”) comparison et seq.

To compare magic square \(a\) with magic square \(b\), their elements are compared in rowwise order: \(a[1,1]\) is compared with \(b[1,1]\), then \(a[1,2]\) with \(b[1,2]\), up to \(a[n,n]\). Consider the first element that is different, say \([i,j]\). Then \(a < b\) if \(a[i,j] < b[i,j]\).

The generalization to hypercubes is straightforward: comparisons are carried out natural order.

Usage

\begin{verbatim}
eq(m1, m2)
ne(m1, m2)
gt(m1, m2)
lt(m1, m2)
ge(m1, m2)
le(m1, m2)
m1 %eq% m2
m1 %ne% m2
m1 %gt% m2
m1 %lt% m2
m1 %ge% m2
m1 %le% m2
\end{verbatim}

Arguments

\begin{verbatim}
m1  First magic square
m2  Second magic square
\end{verbatim}
Note

Rather clumsy function definition due to the degenerate case of testing two identical matrices \( \min(\text{NULL}) \) is undefined.
The two arguments are assumed to be matrices of the same size. If not, an error is given.

fnsd

First non-singleton dimension

Description

Given an array, returns the first non-singleton dimension. Useful for emulating some of Matlab / Octave's multidimensional functions.

If \( n \) is supplied, return the first \( n \) nonsingleton dimensions.

Usage

\[
fnsd(a,n)
\]

Arguments

- \( a \) An array
- \( n \) Integer. Return the first \( n \) nonsingleton dimensions

Value

Returns an integer vector with elements in the range 1 to \( \text{length}(\text{dim}(a)) \).

Note

Treats zero-extent dimensions as singletons.

Case \( n=0 \) now treated sensibly (returns a zero-length vector).

---

**force.integer**  
**Integerize array elements**

**Description**
Returns an elementwise `as.integer`-ed array. All magic squares should have integer elements.

**Usage**
```r
force.integer(x)
```

**Arguments**
- `x` Array to be converted

**Note**
Function `force.integer()` differs from `as.integer()` as the latter returns an integer vector, and the former returns an array whose elements are integer versions of `x`; see examples section below.

\begin{verbatim}
  hudson
  Pandiagonal magic squares due to Hudson
\end{verbatim}

Description

Returns a regular pandiagonal magic square of order $6m \pm 1$ using a method developed by Hudson.

Usage

\begin{verbatim}
  hudson(n = NULL, a = NULL, b = NULL)
\end{verbatim}

Arguments

- \texttt{n} \hspace{1cm} Order of the square, $n = 6m \pm 1$. If \texttt{NULL}, use the length of \texttt{a}
- \texttt{a} \hspace{1cm} The first line of Hudson’s $A$ matrix. If \texttt{NULL}, use Hudson’s value of $c(n-1,0:(n-2))$
- \texttt{b} \hspace{1cm} The first line of Hudson’s $B$ matrix. If \texttt{NULL}, use Hudson’s value of $c(2:(n-1),n,1)$.

Using default values for \texttt{a} and \texttt{b} gives an associative square

Details

Returns one member of a set of regular magic squares of order $n = 6m \pm 1$. The set is of size $(n!)^2$.

Note that $n$ is not checked for being in the form $6n \pm 1$. If it is not the correct form, the square is magic but not necessarily normal.

is.magic 
Various tests for the magicness of a square

Description
Returns TRUE if the square is magic, semimagic, panmagic, associative, normal. If argument give.answers is TRUE, also returns additional information about the sums.

Usage
is.magic(m, give.answers = FALSE, func=sum, boolean=FALSE)
is.panmagic(m, give.answers = FALSE, func=sum, boolean=FALSE)
is.pandiagonal(m, give.answers = FALSE, func=sum, boolean=FALSE)
is.semimagic(m, give.answers = FALSE, func=sum, boolean=FALSE)
is.semimagic.default(m)
is.associative(m)
is.normal(m)
is.sparse(m)
is.mostperfect(m,give.answers=FALSE)
is.2x2.correct(m,give.answers=FALSE)
is.bree.correct(m,give.answers=FALSE)
is.latin(m,give.answers=FALSE)
is.antimagic(m,give.answers = FALSE, func=sum)
is.totally.antimagic(m, give.answers = FALSE, func=sum)
is.heterosquare(m, func=sum)
is.totally.heterosquare(m, func=sum)
is.sam(m)
is.stam(m)
is.magic

Arguments

- **m**: The square to be tested
- **give.answers**: Boolean, with TRUE meaning return additional information about the sums (see details)
- **func**: A function that is evaluated for each row, column, and unbroken diagonal
- **boolean**: Boolean, with TRUE meaning that the square is deemed magic, semimagic, etc, if all applications of func evaluate to TRUE. If boolean is FALSE, square m is magic etc if all applications of func are identical

Details

- A **semimagic square** is one all of whose row sums equal all its columnwise sums (ie the magic constant).
- A **magic square** is a semimagic square with the sum of both unbroken diagonals equal to the magic constant.
- A **panmagic square** is a magic square all of whose broken diagonals sum to the magic constant. Ollerenshaw calls this a “pandiagonal” square.
- A **most-perfect** square has all 2-by-2 arrays anywhere within the square summing to $2S$ where $S = n^2 + 1$; and all pairs of integers $n/2$ distant along the same major (NW-SE) diagonal sum to $S$ (note that the $S$ used here differs from Ollerenshaw’s because her squares are numbered starting at zero). The first condition is tested by **is.2x2.correct()** and the second by **is.bree.correct()**. All most-perfect squares are panmagic.
- A **normal square** is one that contains $n^2$ consecutive integers (typically starting at 0 or 1).
- A **sparse** matrix is one whose nonzero entries are consecutive integers, starting at 1.
- An **associative square** (also **regular square**) is a magic square in which $a_{i,j} + a_{n+1-i,n+1-j} = n^2+1$. Note that an associative semimagic square is magic; see also **is.square.palindromic()**. The definition extends to magic hypercubes: a hypercube a is associative if $a+arev(a)$ is constant.
- An **ultramagic square** is pandiagonal and associative.
- A **latin square** of size $n \times n$ is one in which each column and each row comprises the integers 1 to n (not necessarily in that order). Function **is.latin()** is a wrapper for **is.latinhypercube()** because there is no natural way to present the extra information given when **give.answers** is TRUE in a manner consistent with the other functions documented here.
- An **antimagic square** is one whose row sums and column sums are consecutive integers; a **totally antimagic square** is one whose row sums, column sums, and two unbroken diagonals are consecutive integers. Observe that an antimagic square is not necessarily totally antimagic, and vice-versa.
- A **heterosquare** has all rowsums and column sums distinct; a **totally heterosquare** [NB non-standard terminology] has all rowsums, columnsums, and two long diagonals distinct.
- A square is **sam** (or **SAM**) if it is sparse and antimagic; it is **stam** (or **STAM**) if it is sparse and totally antimagic. See documentation at **SAM**.
Value

Returns TRUE if the square is semimagic, etc. and FALSE if not.

If give.answers is taken as an argument and is TRUE, return a list of at least five elements. The first element of the list is the answer: it is TRUE if the square is (semimagic, magic, panmagic) and FALSE otherwise. Elements 2-5 give the result of a call to allsums(), viz: rowwise and columnwise sums; and broken major (ie NW-SE) and minor (ie NE-SW) diagonal sums.

Function is.bree.correct() also returns the sums of elements distant n/2 along a major diagonal (diag.sums); and function is.2x2.correct() returns the sum of each 2x2 submatrix (tbt.sums); for other size windows use subsums() directly. Function is.mostperfect() returns both of these.

Function is.semimagic.default() returns TRUE if the argument is semimagic [with respect to sum()] using a faster method than is.semimagic().

Note

Functions that take a func argument apply that function to each row, column, and diagonal as necessary. If func takes its default value of sum(), the sum will be returned; if prod(), the product will be returned, and so on. There are many choices for this argument that produce interesting tests; consider func=max, for example. With this, a “magic” square is one whose row, sum and (unbroken) diagonals have identical maxima. Thus diag(5) is magic with respect to max(), but diag(6) isn’t.

Argument boolean is designed for use with non-default values for the func argument; for example, a latin square is semimagic with respect to func=function(x){all(diff(sort(x))==1)}.

Function is.magic() is vectorized; if a list is supplied, the defaults are assumed.

is.latinhypercube(a, give.answers=FALSE)
is.alicehypercube(a,ndim,give.answers=FALSE, func=sum, boolean=FALSE)

Arguments

a              The hypercube (array) to be tested
give.answers  Boolean, with TRUE meaning to also return the sums
func           Function to be applied across each dimension
ndim           In is.alicehypercube(), dimensionality of subhypercube to take sums over. See the details section
boolean        Boolean, with TRUE meaning that the hypercube is deemed magic, semimagic, etc, if all applications of func evaluate to TRUE. If boolean is FALSE, the hypercube is magic etc if all applications of func are identical
...

Further arguments passed to func()

Details

(Although apparently non-standard, here a hypercube is defined to have dimension $d$ and order $n$—and thus has $n^d$ elements).

- A semimagic hypercube has all “rook’s move” sums equal to the magic constant (that is, each $\sum d[i_1, i_2, \ldots, i_{r-1}, i_{r+1}, \ldots, i_d]$ with $1 \leq r \leq d$ is equal to the magic constant for all values of the $i$’s). In is.semimagichypercube(), if give.answers is TRUE, the sums returned are in the form of an array of dimension $c(rep(n,d-1),d)$. The first $d-1$ dimensions are the coordinates of the projection of the summed elements onto the surface hypercube. The last dimension indicates the dimension along which the sum was taken over. Optional argument func, defaulting to sum(), indicates the function to be taken over each of the $d$ dimensions. Currently requires func to return a scalar.
• A Latin hypercube is one in which each line of elements whose coordinates differ in only one dimension comprises the numbers 1 to \( n \) (or 0 to \( n-1 \)), not necessarily in that order. Each integer thus appears \( n^{d-1} \) times.

• A magic hypercube is a semimagic hypercube with the additional requirement that all \( 2^{d-1} \) long (ie extreme point-to-extreme point) diagonals sum correctly. Correct diagonal summation is tested by \texttt{is.diagonally.correct()}; by specifying a function other than \texttt{sum()}, criteria other than the diagonals returning the correct sum may be tested.

• An Alice hypercube is a different generalization of a semimagic square to higher dimensions. It is named for A. M. Hankin (“Alice”), who originally suggested it.

A semimagic hypercube has all one-dimensional subhypercubes (ie lines) summing correctly. An Alice hypercube is one in which all \( n \times d \) subhypercubes have the same sum, where \( ndim \) is a fixed integer argument. Thus, if \( a \) is a hypercube of size \( n^d \), \texttt{is.alicehypercube(a,ndim)} returns \texttt{TRUE} if all \( n^{d-ndim} \) subhypercubes have the same sum.

For example, if \( a \) is four-dimensional with dimension \( 5 \times 5 \times 5 \times 5 \) then \texttt{is.alicehypercube(a,1)} is \texttt{TRUE} if and only if \( a \) is a semimagic hypercube: all \( \binom{4}{1}5^3 = 500 \) one-dimensional subhypercubes have the same sum. Then \texttt{is.alicehypercube(a,2)} is \texttt{TRUE} if all 2-dimensional subhypercubes (ie all \( \binom{4}{2}5^2 = 150 \) of the \( 5 \times 5 \) squares, for example \( a[2,4,\ldots] \)) have the same sum. Then \texttt{is.alicehypercube(a,3)} means that all 3d subhypercubes (ie all \( \binom{4}{3}5 = 20 \) of the \( 5 \times 5 \times 5 \) cubes, for example \( a[1,1,\ldots] \) and \( a[4,4,\ldots] \)) have the same sum. For any hypercube \( a \), \texttt{is.alicehypercube(a,dim(a))} returns \texttt{TRUE}.

A semimagic hypercube is an Alice hypercube for any value of \( ndim \).

• A perfect magic hypercube (use \texttt{is.perfect()}) is a magic hypercube with all nonbroken diagonals summing correctly. This is a seriously restrictive requirement for high dimensional hypercubes. As yet, this function does not take a \texttt{give.answers} argument.

• A pandiagonal magic hypercube, also Nasik hypercube (or sometimes just a perfect hypercube) is a semimagic hypercube with all diagonals, including broken diagonals, summing correctly. This is not implemented.

The terminology in this area is pretty confusing.

In \texttt{is.magichypercube()}, if argument \texttt{give.answers=TRUE} then a list is returned. The first element of this list is Boolean with \texttt{TRUE} if the array is a magic hypercube. The second element and third elements are answers from \texttt{is.semimagichypercube()} and \texttt{is.diagonally.correct()} respectively.

In \texttt{is.diagonally.correct()}, if argument \texttt{give.answers=TRUE}, the function also returns an array of dimension \( c(q,\text{rep}(2,d)) \) (that is, \( q \times 2^d \) elements), where \( q \) is the length of \texttt{func()} applied to a long diagonal of \( a \) (if \( q = 1 \), the first dimension is dropped). If \( q = 1 \), then in dimension \( d \) having index 1 means \texttt{func()} is applied to elements of \( a \) with the \( d \)th dimension running over \( 1:n \); index 2 means to run over \( n:1 \). If \( q > 1 \), the index of the first dimension gives the index of \texttt{func()}, and subsequent dimensions have indices of 1 or 2 as above and are interpreted in the same way.

An example of a function for which these two are not identical is given below.

If \texttt{func=f} where \( f \) is a function returning a vector of length \( i \), \texttt{is.diagonally.correct()} returns an array out of dimension \( c(i,\text{rep}(2,d)) \), with \texttt{out[i_1,i_2,\ldots,i_d]} being \( f(x) \) where \( x \) is the appropriate long diagonal. Thus the \( 2^d \) equalities \texttt{out[i_1,i_2,\ldots,i_d]==out[3-i_1,3-i_2,\ldots,3-i_d]} hold if and only if \texttt{identical(f(x),f(rev(x))} is \texttt{TRUE} for each long diagonal (a condition met, for example, by \texttt{sum()} but not by the identity function or \texttt{function(x){x[1]}}).
Note

On this page, “subhypercube” is restricted to rectangularly-oriented subarrays; see the note at subhypercubes.

Not all subhypercubes of a magic hypercube are necessarily magic! (for example, consider a 5-dimensional magic hypercube \(a\). The square \(b\) defined by \(a[1,1,1,,]\) might not be magic: the diagonals of \(b\) are not covered by the definition of a magic hypercube). Some subhypercubes of a magic hypercube are not even semimagic: see below for an example.

Even in three dimensions, being perfect is pretty bad. Consider a \(5 \times 5 \times 5\) (ie three dimensional), cube. Say \(a=magickcube.2np1(2)\). Then the square defined by \(sapply(1:n, function(i)\{a[i,1,6-i]\}, simplify=TRUE)\), which is a subhypercube of \(a\), is not even semimagic: the rowsums are incorrect (the colsums must sum correctly because \(a\) is magic). Note that the diagonals of this square are two of the “extreme point-to-point” diagonals of \(a\).

A pandiagonal magic hypercube (or sometimes just a perfect hypercube) is semimagic and in addition the sums of all diagonals, including broken diagonals, are correct. This is one seriously bad-ass requirement. I reckon that is a total of \(\frac{1}{2} (3^d - 1) \cdot n^{d-1}\) correct summations. This is not coded up yet; I can’t see how to do it in anything like a vectorized manner.

</tr>
</tbody>
</table>
is.square.palindromic

Author(s)
Robin K. S. Hankin

Examples
is.ok(magic(5)[1,])

is.sqare.palindromic  Is a square matrix square palindromic?

Description
Implementation of various properties presented in a paper by Arthur T. Benjamin and K. Yasuda

Usage
is.square.palindromic(m, base=10, give.answers=FALSE)
is.centrosymmetric(m)
is.persymmetric(m)

Arguments
m  The square to be tested
base Base of number expansion, defaulting to 10; not relevant for the “sufficient” part of the test
give.answers Boolean, with TRUE meaning to return additional information

Details
The following tests apply to a general square matrix m of size $n \times n$.

- A **centrosymmetric** square is one in which $a[i,j]=a[n+1-i,n+1-j]$; use is.centrosymmetric() to test for this (compare an **associative** square). Note that this definition extends naturally to hypercubes: a hypercube a is centrosymmetric if all(a==arev(a)).
- A **persymmetric** square is one in which $a[i,j]=a[n+1-j,n+1-i]$; use is.persymmetric() to test for this.
- A matrix is **square palindromic** if it satisfies the rather complicated conditions set out by Benjamin and Yasuda (see refs).
Value

These functions return a list of Boolean variables whose value depends on whether or not m has the property in question.

If argument give.answers takes the default value of FALSE, a Boolean value is returned that shows whether the sufficient conditions are met.

If argument give.answers is TRUE, a detailed list is given that shows the status of each individual test, both for the necessary and sufficient conditions. The value of the second element (named necessary) is the status of their Theorem 1 on page 154.

Note that the necessary conditions do not depend on the base b (technically, neither do the sufficient conditions, for being a square palindrome requires the sums to match for every base b. In this implementation, “sufficient” is defined only with respect to a particular base).

Note

Every associative square is square palindromic, according to Benjamin and Yasuda.

Function is.square.palindromic() does not yet take a give.answers argument as does, say, is.magic().

Author(s)

Robin K. S. Hankin

Examples

```r
is.square.palindromic(magic(3))
is.persymmetric(matrix(c(1,0,0,1),2,2))
```

```r
#now try a circulant:
a <- matrix(0,5,5)
is.square.palindromic(circulant(10)) #should be TRUE
```

Description

Various functionality for generating random latin squares
Usage

incidence(a)
is.incidence(a, include.improper)
is.incidence.improper(a)
unincidence(a)
inc_to_inc(a)
another_latin(a)
another.incidence(i)
rlatin(n, size=NULL, start=NULL, burnin=NULL)

Arguments

a

A latin square

i

An incidence array

n, include.improper, size, start, burnin

Various control arguments; see details section

Details

- Function incidence() takes an integer array (specifically, a latin square) and returns the incidence array as per Jacobson and Matthew 1996
- Function is.incidence() tests for an array being an incidence array; if argument include.improper is TRUE, admit an improper array
- Function is.incidence.improper() tests for an array being an improper array
- Function unincidence() converts an incidence array to a latin square
- Function another_latin() takes a latin square and returns a different latin square
- Function another.incidence() takes an incidence array and returns a different incidence array
- Function rlatin() generates a (Markov) sequence of random latin squares, arranged in a 3D array. Argument n specifies how many to generate; argument size gives the size of latin squares generated; argument start gives the start latin square (it must be latin and is checked with is.latin()); argument burnin gives the burn-in value (number of Markov steps to discard).

Default value of NULL for argument size means to take the size of argument start; default value of NULL for argument start means to use circulant(size)

As a special case, if argument size and start both take the default value of NULL, then argument n is interpreted as the size of a single random latin square to be returned; the other arguments take their default values. This ensures that “rlatin(n)” returns a single random

n × n latin square.

From Jacobson and Matthew 1996, an n × n latin square LS is equivalent to an n × n × n array A with entries 0 or 1; the dimensions of A are identified with the rows, columns and symbols of LS; a 1 appears in cell (r, c, s) of A iffi the symbol s appears in row r, column c of LS. Jacobson and Matthew call this an incidence cube.

The notation is readily generalized to latin hypercubes and incidence() is dimensionally vectorized.
An improper incidence cube is an incidence cube that includes a single $-1$ entry; all other entries must be 0 or 1; and all line sums must equal 1.

best_latin <- matrix(jj$par,7,7)
print(best_latin)
print(f(best_latin))

#compare starting value:
f(circulant(7))

---

lozenge

_Conway’s lozenge algorithm for magic squares_

**Description**

Uses John Conway’s lozenge algorithm to produce magic squares of odd order.

**Usage**

lozenge(m)
magic

Arguments

\( n \) magic square returned is of order \( n=2m+1 \)

Author(s)

Robin Hankin

See Also

\texttt{magic.4np2}

Examples

\begin{verbatim}
lozenge(4)
all(sapply(1:10, function(n) {is.magic(lozenge(n))}))
\end{verbatim}

\begin{verbatim}
magic

Creates magic squares

Description

Creates normal magic squares of any order \( > 2 \). Uses the appropriate method depending on \( n \) modulo 4.

Usage

\texttt{magic(n)}

Arguments

\( n \) Order of magic square. If a vector, return a list whose \( i \)-th element is a magic square of order \( n[i] \)

Details

Calls either \texttt{magic.2np1()}, \texttt{magic.4n()}, or \texttt{magic.4np2()} depending on the value of \( n \). Returns a magic square in standard format (compare the \texttt{magic.2np1()} et seq, which return the square as generated by the direct algorithm).

Author(s)

Robin K. S. Hankin

References

Examples

magic(6)
all(is.magic(magic(3:10)))

## The first eigenvalue of a magic square is equal to the magic constant:
eigen(magic(10), FALSE, TRUE)$values[1] - magic.constant(10)

## The sum of the eigenvalues of a magic square after the first is zero:
sum(eigen(magic(10), FALSE, TRUE)$values[2:10])

---

**magic.2np1**

*Magic squares of odd order*

Description

Function to create magic squares of odd order

Usage

magic.2np1(m, ord.vec = c(-1, 1), break.vec = c(1, 0), start.point=NULL)

Arguments

- **m**
  - creates a magic square of order \( n = 2m + 1 \)

- **ord.vec**
  - ordinary vector. Default value of \( c(-1,1) \) corresponds to the usual northeast direction

- **break.vec**
  - break vector. Default of \( c(1,0) \) corresponds to the usual south direction

- **start.point**
  - Starting position for the method (ie coordinates of unity). Default value of NULL corresponds to row 1, column \( m \)

Author(s)

Robin K. S. Hankin

References

Written up in loads of places. The method (at least with the default ordinary and break vectors) seems to have been known since at least the Renaissance.

Benson and Jacoby, and the Mathematica website, discuss the problem with nondefault ordinary and break vectors.
See Also

`magic, magic.prime`

Examples

```r
f <- function(n){is.magic(magic.2np1(n))}
all(sapply(1:20,f))

is.panmagic(magic.2np1(5,ord.vec=c(2,1),break.vec=c(1,3)))
```

---

**magic.4n**  
*Magic squares of order 4n*

**Description**

Produces an associative magic square of order 4n using the delta-x method.

**Usage**

`magic.4n(m)`

**Arguments**

- `m` Order n of the square is given by `n = 4m`

**Author(s)**

Robin K. S. Hankin

**See Also**

`magic`

**Examples**

```r
magic.4n(4)
is.magic(magic.4n(5))
```
Description

Produces a magic square of order \( 4n + 2 \) using Conway’s “LUX” method.

Usage

\[
magic.4np2(m)
\]

Arguments

\( m \) returns a magic square of order \( n = 4m + 2 \) for \( m \geq 1 \), using Conway’s “LUX” construction.

Note

I am not entirely happy with the method used: it’s too complicated.

Author(s)

Robin K. S. Hankin

magic

Examples

\[
magic.4np2(1)
is.magic(magic.4np2(3))
\]
Regular magic squares of order 8

Description

Returns all 90 regular magic squares of order 8

Usage

magic.8(...)  

Arguments

... ignored

Value

Returns an array of dimensions c(8,8,90) of which each slice is an 8-by-8 magic square.

Author(s)

Robin K. S. Hankin

References

Examples

```r
## Not run:
h <- magic.8()
h[,1]
is.magic(h[,4])

## End(Not run)
```

Magic constant of a magic square or hypercube

Description

Returns the magic constant: that is, the common sum for all rows, columns and (broken) diagonals of a magic square or hypercube
Usage

magic.constant(n,d=2,start=1)

Arguments

n       Order of the square or hypercube

Arguments

n       Order of the square or hypercube
d       Dimension of hypercube, defaulting to d=2 (a square)
start   Start value. Common values are 0 and 1

Details

If n is an integer, interpret this as the order of the square or hypercube; return \( n(\text{start} + n^d - 1)/2 \).
If n is a square or hypercube, return the magic constant for a normal array (starting at 1) of the same dimensions as n.

Author(s)

Robin K. S. Hankin

magic

Examples

magic.constant(4)

---

magic.prime  Magic squares prime order

---

Description

Produces magic squares of prime order using the standard method

Usage

magic.prime(n,i=2,j=3)

Arguments

n       The order of the square
i       row number of increment
j       column number of increment
Details

Claimed to work for prime order, but I’ve tried it (with the defaults for i and j) for many composite integers of the form $6n + 1$ and $6n - 1$ and found no exceptions; indeed, they all seem to be panmagic. It is not clear to me when the process works and when it doesn’t.

Author(s)

Robin K. S. Hankin

Examples

```r
magic.prime(7)
f <- function(n){is.magic(magic.prime(n))}
all(sapply(6*1:30+1,f))
all(sapply(6*1:30-1,f))

is.magic(magic.prime(9,i=2,j=4),give.answers=TRUE)
magic.prime(7,i=2,j=4)
```

---

**magic.product**

*Product of two magic squares*

**Description**

Gives a magic square that is a product of two magic squares.

**Usage**

`magic.product(a, b, mat=NULL)`

`magic.product.fast(a, b)`

**Arguments**

- `a`  
  First magic square; if a is an integer, use `magic(a)`.

- `b`  
  as above

- `mat`  
  Matrix, of same size as a, of integers treated as modulo 8. Default value of NULL equivalent to passing a*0. Each number from 0-7 corresponds to one of the 8 squares which have the same Frenicle’s standard form, as generated by `transfH()`). Then subsquares of the product square (ie tiles of the same size as b) are rotated and transposed appropriately according to their corresponding entry in mat. This is a lot easier to see than to describe (see examples section).
Details

Function `magic.product.fast()` does not take a mat argument, and is equivalent to `magic.product()` with mat taking the default value of NULL. The improvement in speed is doubtful unless \( \text{order}(a) \gg \text{order}(b) \), in which case there appears to be a substantial saving.

magic

Examples

#try with m=3, n=2*3+1=7:

m <- 7
n <- 2*m+1

apply(magiccube.2np1(m),c(1,2),sum)
apply(magiccube.2np1(m),c(1,3),sum)
apply(magiccube.2np1(m),c(2,3),sum)

#major diagonal checks out:
sum(magiccube.2np1(m)[matrix(1:n,n,3)])

#now other diagonals:
b <- c(-1,1)
f <- function(dir,v){if(dir>0){return(v)}else{return(rev(v))}}
g <- function(jj){sum(magiccube.2np1(m)[sapply(jj,f,v=1:n)])}
apply(expand.grid(b,b,b),1,g)  #each diagonal twice, once per direction.

Description

A list of four elements listing each fundamentally different magic cube of order 3

Usage

data(magiccubes)

Source

Originally discovered by Hendricks

Examples

data(magiccubes)
magiccubes$a1
sapply(magiccubes,is.magichypercube)
magichypercube.4n  Magic hypercubes of order 4n

Description

Returns magic hypercubes of order 4n and any dimension.

Usage

magichypercube.4n(m, d = 3)

Arguments

m  Magic hypercube produced of order \( n = 4m \)
d  Dimensionality of cube

Details

Uses a rather kludgy (but vectorized) method. I am not 100% sure that the method does in fact produce magic squares for all orders and dimensions.

Author(s)

Robin K. S. Hankin

Examples

magichypercube.4n(1,d=4)
magichypercube.4n(2,d=3)

magicplot  Joins consecutive numbers of a magic square.

Description

A nice way to graphically represent normal magic squares. Lines are plotted to join successive numbers from 1 to \( n^2 \). Many magic squares have attractive such plots.

Usage

magicplot(m, number = TRUE, do.circuit = FALSE, ...)

magichypercube.4n

magichypercube.4n
Arguments

- **m** Magic square to be plotted.
- **number** Boolean variable with TRUE meaning to include the numbers on the plot
- **do.circuit** Boolean variable with TRUE meaning to include the line joining \( n^2 \) to 1
- ... Extra parameters passed to plot()

Author(s)

Robin K. S. Hankin

Examples

- `magicplot(magic.4n(2))`

---

**minmax**

*are all elements of a vector identical?*

Description

Returns TRUE if and only if all elements of a vector are identical.

Usage

- `minmax(x, tol=1e-6)`

Arguments

- **x** Vector to be tested
- **tol** Relative tolerance allowed

Details

If `x` is an integer, exact equality is required. If real or complex, a relative tolerance of `tol` is required. Note that functions such as `is.magic()` and `is.semi_magic_hypercube()` use the default value for `tol`. To change this, define a new Boolean function that tests the sum to the required tolerance, and set `boolean` to TRUE

Author(s)

Robin K. S. Hankin

See Also

- `is.magic()`

Examples

- `data(0llerenshaw)`
- `minmax(subsums(0llerenshaw,2))` #should be TRUE, as per is.2x2.correct()`
notmagic.2n  An unmagic square

Description

Returns a square of order \( n = 2m \) that has been claimed to be magic, but isn’t.

Usage

\[
\text{notmagic.2n}(m)
\]

Arguments

\( m \)  Order of square is \( n = 2m \)

Note

This took me a whole evening to code up. And I was quite pleased with the final vectorized form: it matches Andrews’s (8 by 8) example square exactly. What a crock

Author(s)

Robin K. S. Hankin

References

Examples

\[
\text{notmagic.2n}(4)
\]
\[
\text{is.magic(notmagic.2n(4))}
\]

`data(Ollerenshaw)`

`is.mostperfect(Ollerenshaw)`

---

Panmagic squares of order 4

*Description*

Creates all fundamentally different panmagic squares of order 4.

*Usage*

`panmagic.4(vals = 2^(0:3))`

*Arguments*

`vals`  
A length four vector giving the values which are combined in each of the $2^4$ possible ways. Thus `vals=2^sample(0:3)` always gives a normal square (0-15 in binary).

*Author(s)*

Robin K. S. Hankin

panmagic.6npm1

Examples

panmagic.4()
panmagic.4(2^c(1,3,2,0))
panmagic.4(10^c(0:3))

Description

Produce a panmagic square of order 4n or 6n ± 1 using a classical method

Usage

panmagic.6npm1(n)
panmagic.6np1(m)
panmagic.6nn1(m)
panmagic.4n(m)

Arguments

m Function panmagic.6np1(m) returns a panmagic square of order \( n = 6m + 1 \) for \( m \geq 1 \), and function panmagic.6nn1(m) returns a panmagic square of order \( n = 6m - 1 \) for \( m \geq 1 \), using a classical method.
Function panmagic.4n(m) returns a magic square of order \( n = 4m \)

n Function panmagic.6npm1(n) returns a panmagic square of order \( n \) where \( n = 6m \pm 1 \)

Details

Function panmagic.6npm1(n) will return a square if \( n \) is not of the form \( 6m \pm 1 \), but it is not necessarily magic.

process  

**Force index arrays into range**

**Description**
Forces an (integer) array to have entries in the range 1-n, by (i) taking the entries modulo n, then (ii) setting zero elements to n. Useful for modifying index arrays into a form suitable for use with magic squares.

**Usage**

```r
process(x, n)
```

**Arguments**

- `x`: Index array to be processed
- `n`: Modulo of arithmetic to be used

**Author(s)**

Robin K. S. Hankin

**Examples**

```r
# extract the broken diagonal of magic.2np1(4) that passes through element [1,5]:

a <- magic.2np1(4)
index <- t(c(1,5)+c(1:9,1:9))
a[process(index,9)]
```

---

**recurse**  

**Recursively apply a permutation**

**Description**
Recursively apply a permutation to a vector an arbitrary number of times. Negative times mean apply the inverse permutation.

**Usage**

```r
recurse(perm, i, start = seq_along(perm))
```
Arguments

 perm  Permutation (integers 1 to length(start) in some order)
 start  Start vector to be permuted
 i  Number of times to apply the permutation. i=0 gives start by definition and
 negative values use the inverse permutation

Author(s)

 Robin K. S. Hankin

 hudson

Examples

 n <- 15
 noquote(recurse(start=letters[1:n], perm=shift(1:n), i=0))
 noquote(recurse(start=letters[1:n], perm=shift(1:n), i=1))
 noquote(recurse(start=letters[1:n], perm=shift(1:n), i=2))

 noquote(recurse(start=letters[1:n], perm=sample(n), i=1))
 noquote(recurse(start=letters[1:n], perm=sample(n), i=2))

Description

 Produces an antimagic square of order m using Gray and MacDougall’s method.

Usage

 sam(m, u, A=NULL, B=A)

Arguments

 m  Order of the magic square (not “n”: the terminology follows Gray and Mac-
 Dougall)
 u  See details section
 A,B  Start latin squares, with default NULL meaning to use circulant(m)
Details

In Gray’s terminology, sam(m,n) produces a $SAM(2m, 2u + 1, 0)$.
The method is not vectorized.

To test for these properties, use functions such as is.antiMagic(), documented under is.magic.Rd.

Author(s)

Robin K. S. Hankin

References

See Also

magic, is.magic

Examples

sam(6,2)

jj <- matrix(c(
  5, 2, 3, 4, 1,
  3, 5, 4, 1, 2, 
  2, 3, 1, 5, 4, 
  4, 1, 2, 3, 5, 
  1, 4, 5, 2, 3),5,5)

is.sam(sam(5,2,B=jj))

Description

Shift origin of arrays and vectors.

Usage

shift(x, i=1)
ashift(a, v=rep(1,length(dim(a))))
Arguments

- \( x \) : Vector to be shifted
- \( i \) : Number of places elements to be shifted, with default value of 1 meaning to put the last element first, followed by the first element, then the second, etc
- \( a \) : Array to be shifted
- \( v \) : Vector of numbers to be shifted in each dimension, with default value corresponding to shifting each dimension by 1 unit. If the length of \( v \) is less than \( \text{length}(\text{dim}(a)) \), it is padded with zeros (thus a scalar value of \( i \) indicates that the first dimension is to be shifted by \( i \) units)

Details

Function \( \text{shift}(x, n) \) returns \( P^n(x) \) where \( P \) is the permutation \( (n, 1, 2, \ldots, n - 1) \).

Function \( \text{ashift} \) is the array generalization of this: the \( n \)th dimension is shifted by \( v[n] \). In other words, \( \text{ashift}(a, v) = a[\text{shift}(1: \text{dim}(a)[1], v[1]), \ldots, \text{shift}(1: \text{dim}(a)[n], v[n])] \). It is named by analogy with \( \text{abind()} \) and \( \text{aperm()} \).

This function is here because a shifted semimagic square or hypercube is semimagic and a shifted pandiagonal square or hypercube is pandiagonal (note that a shifted magic square is not necessarily magic, and a shifted perfect hypercube is not necessarily perfect).

Author(s)

Robin K. S. Hankin

Examples

```r
shift(1:10, 3)
m <- matrix(1:100, 10, 10)
ashift(m, c(1, 1))
ashift(m, c(0, 1))  # note columns shifted by 1, rows unchanged.
ashift(m, dim(m))   # m unchanged (Mnemonic).
```

---

**strachey**  
*Strachey’s algorithm for magic squares*

Description

Uses Strachey’s algorithm to produce magic squares of singly-even order.

Usage

```r
strachey(m, square=magic.2np1(m))
```
Arguments

- **m**: Magic square produced of order \(n=2m+1\)
- **square**: Magic square of order \(2m+1\) needed for Strachey’s method. Default value gives the standard construction, but the method will work with any odd order magic square.

Details

Strachey’s method essentially places four identical magic squares of order \(2m+1\) together to form one of \(n = 4m + 2\). Then \(0, n^2/4, n^2/2, 3n^2/4\) is added to each square; and finally, certain squares are swapped from the top subsquare to the bottom subsquare.

See the final example for an illustration of how this works, using a zero matrix as the submatrix. Observe how some 75s are swapped with some 0s, and some 50s with some 25s.

Author(s)

Robin K. S. Hankin

Examples

```r
strachey(3)
strachey(2, square=magic(5))

strachey(2, square=magic(5)) %eq% strachey(2, square=t(magic(5)))
# should be FALSE

# Show which numbers have been swapped:
strachey(2, square=matrix(0, 5, 5))

# It's still magic, but not normal:
is.magic(strachey(2, square=matrix(0, 5, 5)))
```

---

### Sums of submatrices

**Description**

Returns the sums of submatrices of an array; multidimensional moving window averaging.

**Usage**

```
subsums(a, p, func="sum", wrap=TRUE, pad=0)
```
Arguments

a  Array to be analysed
p  Argument specifying the subarrays to be summed. If a vector of length greater than one, it is assumed to be of length \( d = \text{length}(\text{dim}(a)) \), and is interpreted to be the dimensions of the subarrays, with the size of the window’s \( n^{th} \) dimension being \( a[n] \). If the length of \( p \) is one, recycling is used.
If not a vector, is assumed to be a matrix with \( d \) columns, each row representing the coordinates of the elements to be summed. See examples.

func Function to be applied over the elements of the moving window. Default value of \text{sum} gives the sum as used in \text{is.2x2.correct}(); other choices might be \text{mean}, \text{prod}, or \text{max}.
If \text{sum} is not used, return the array of dimension \( c(\text{dim}(a), \text{prod}(p)) \) where each hyperplane is a shifted version of \( a \).

wrap Boolean, with default value of TRUE meaning to view array \( a \) as a \( n \)-dimensional torus. Thus, if \( x = \text{subsums}(a, p, \text{wrap} = \text{TRUE}) \), and if \( \text{dim}(a) = c(a_1, \ldots , a_d) \) then \( x[a_1, \ldots , a_d] \) is the sum of all corner elements of \( a \).
If \text{FALSE}, do not wrap \( a \) and return an array of dimension \( \text{dim}(a) + p - 1 \).

pad If \text{wrap} is TRUE, pad is the value used to pad the array with. Use a “neutral” value here; for example, if \text{func} = \text{sum}, then use 0; if \text{max}, use \(-\infty\).

Details
The offset is specified so that \[ \text{allsums}(a, v)[1, 1, \ldots , 1] = \text{sum}(a[1:v[1], 1:v[2], \ldots , 1:v[n]]), \] where \( n = \text{length}(\text{dim}(a)) \).
Function \text{subsums}() is used in \text{is.2x2.correct}() and \text{is.diagonally.correct}().

Author(s)
Robin K. S. Hankin

Examples

\begin{verbatim}
data(Ollerenshaw)
subsums(Ollerenshaw, c(2,2))
subsums(Ollerenshaw[,1:10], c(2,2))
subsums(Ollerenshaw, matrix(c(0,6),2,2))  # effectively, is.bree.correct()

# multidimensional example.
a <- array(1, c(3,4,2))
subsums(a, 2)  # note that p=2 is equivalent to p=c(2,2,2);
               # all elements should be identical
subsums(a, 2, wrap=FALSE)  # note "middle" elements > "outer" elements

#Example of nondefault function:
x <- matrix(1:42,6,7)
subsums(x, 2, func="max", pad=Inf, wrap=TRUE)
subsums(x, 2, func="max", pad=Inf, wrap=FALSE)
\end{verbatim}
transf | Frenicle's equivalent magic squares

### Description
For a given magic square, returns one of the eight squares whose Frenicle's standard form is the same.

### Usage
```
transf(a, i)
```

### Arguments
- `a`: Magic square
- `i`: Integer, considered modulo 8. Specifying 0-7 gives a different magic square

### Author(s)
Robin K. S. Hankin

### See Also
